15

16 **Abstract**

17 The late Albian–early Cenomanian oceanic anoxic event 1d (OAE-1d; ~ 103 to

18 99.5 Ma) represents a global interval of enhanced organic carbon burial due to

19 widespread oxygen deficiency in the water column and/or increased primary

20 productivity. The biostratigraphy and geochemistry of organic-rich sediments in the

21 La Grita Member (Capacho Formation) in southwestern Venezuela were studied to

22 document the paleoenvironmental conditions that governed the deposition of this

23 succession during OAE-1d. Carbon-isotope ($\delta^{13}C_{carb}$ and $\delta^{13}C_{Corg}$) chemostratigraphy

24 and biostratigraphic constraints show that the La Grita Member spans the late Aptian

25 period (*Rotalipora appenninica* Zone), and that OAE-1d is well recorded in this

26 succession. A prominent increase in total organic carbon (TOC) values (up to 10%) is

27 clearly recorded through the onset of OAE-1d, coinciding with a prominent change in

overall redox-sensitive proxies suggesting that the La Grita Member sediments accumulated under anoxic (and possibly euxinic) bottom-water conditions in a partially restricted basin. The detrital proxies suggest that the greenhouse climate prevailing during OAE-1d induced significant acceleration of the hydrologic cycle and an increase in continental chemical weathering rates. Overall, the carbon and oxygen isotope records, TOC contents, as well as the detrital proxies show cyclic variation during the late Albian stage. These variations support the hypothesis that orbital forcing likely also modulated the equatorial monsoonal activity during the OAE-1d.

Keywords: Mid-Cretaceous**;** Sedimentary geochemistry; Stable isotopes; Biostratigraphy; Paleoenvironment; Redox conditions.

1. Introduction

The mid-Cretaceous (i.e., Albian–Turonian; 110–90 Ma) is an interval in which an increase in the production of oceanic crust, together with the formation of large igneous provinces, promoted pCO_2 emission to the atmosphere and the conjunction of a greenhouse climate (Arthur et al., 1985; Barron and Washington, 1985; Leckie, 2002; Bodin et al., 2015). As a consequence, high temperatures and the acceleration of the hydrological cycle (Menegatti et al., 1998; Bodin et al., 2015) led to increased primary productivity causing anoxic oceanic conditions (Föllmi et al., 1994; Turgeon and Brumsack, 2006) and producing several distinctive episodes of organic matter accumulation called oceanic anoxic events (OAEs; Jenkyns, 1980). Since such events disturb the carbon cycle, carbon isotope stratigraphy is traditionally used as a marker to recognize oceanic anoxic events (Sholle and Arthur, 1980; Herrle et al., 2004; Jenkyns, 2010)..

53   Most studies of OAEs occurring in the mid Cretaceous have focused on OAE-1a

54   (e.g., Erba, 1994; Menegatti et al., 1998) and on OAE-2 (e.g., Arthur et al., 1987;

55   Gale et al., 1993; Huber et al., 2002). However, less research has been carried out on

56   sub-OAEs such as OAE 1b and 1d because they represent occurrences of organic-rich

57   black shale that are less thick, rather patchy in distribution, and less pronounced

58   isotopic records (e.g., Robinson et al., 2004; Navarro-Ramirez et al., 2015). Unlike

59   the main OAEs of the Mesozoic era (Jenkyns, 2010), OAE-1d is characterized by a

60   moderate (0.5 to 2‰) positive carbon isotope ($\delta^{13}C$) excursion (Wilson and Norris,

61   2001; Bornemann et al., 2005; Watkins et al., 2005; Meyers et al., 2006; Gambacorta,

62   2011; Giorgioni et al., 2012). Thus, coupling carbon isotope with inorganic

63   geochemical proxies could help in the reconstruction of depositional conditions and

64   highlights the occurrence of OAE events when traditional signals may not be as

65   apparent (Erbacher et al., 1999; Scott et al., 2013).

66   The study of OAE-1d has gained importance thanks to the studies of Wilson and

67   Norris (2001), which showed that the "Breistroffer" event (or OAE-1d) was a global

68   event that was the product of the collapse of the stratification of the upper ocean, at

69   least in western tropical Atlantic. More recently, some authors have suggested that

70   OAE-1d was triggered by a period of enhanced orbital forcing, which induced an

71   exceptionally strong seasonal contrast, with resulting unstable circulation that favored

72   the expansion of deep-water anoxic conditions (Bornemann et al., 2005; Giorgioni et

73   al., 2012; Giorgioni et al., 2015).

74   The rocks deposited during the Cretaceous in western Venezuela reflect the

75   combination of different factors, such as relative changes in sea level, the occurrence

76   of OAEs, upwelling currents, and restricted circulation, which are intimately linked to

77   the paleoceanographic, bathymetric characteristics, and climate (Macellari, 1988;

78   Pérez-Infante et al., 1996; Villamil et al., 1999; Erlich et al., 1999a,b). Some of these

79   Cretaceous units have been well correlated with global events, such as the OAE-1a

80   and 1b events represented by the Cogollo Group (Méndez-Dot et al., 2015), and the

81   OAE-2 (Cenomanian-Turonian) represented mainly by the La Luna Formation

82   (Tribovillard et al., 1991; Pérez-Infante et al., 1996; Erlich et al., 1999a,b). The La

83   Grita Member in the Capacho Formation (southwestern Venezuela) is characterized

84   by anoxic facies, dense black limestones intercalated with marly limestones of

85   Albian–Cenomanian age (Renz, 1959). However, there have been no detailed

86   biostratigraphic and geochemical studies documenting the paleoenvironmental

87   sedimentation conditions of this succession, the precise calibration of their age, and

88   their possible correlation with globally recorded anoxic Cretaceous events. Therefore,

89   using biostratigraphic and geochemical tools (such as stable isotope analysis and

90   elemental geochemistry), this work aims not only to investigate the expression of

91   OAE-1d in northwestern South America, but also to better document the main impacts

92   of this event in the depositional environment in the La Grita Member.

93

94   **2. Geological setting**

95   **2.1. Cretaceous stratigraphy of western Venezuela**

96   During the Cretaceous, the western margin of South America was covered by

97   various transgressive cycles, favouring the deposition of rocks of huge economic

98   importance due to their hydrocarbon contents (Macellari, 1988; Erlich et al., 1999a,b).

99   The Mesozoic–Cenozoic stratigraphy sequence established for western Venezuela is a

100   result of the interaction of tectonic and thermal subsidence, variations in sediment

101   sources, and changes in global sea level (Macellari, 1988; Pindell, 1993; Parnaud et

102   al., 1995; Lugo and Mann, 1995). The Pangea Jurassic rifting stage caused various

significant tectonic events that subsequently influenced the evolution of the sedimentary basins. The opening of the Proto-Caribbean caused graben formation (e.g., the Andes, Perijá, and Lake Maracaibo), which were then filled during the Jurassic by lacustrine, fluvial, and volcanic sediments. From the early to late Cretaceous (Fig. 1), the region shifted to a passive continental margin stage, and sedimentation was largely controlled by the Jurassic graben system (González de Juana et al., 1980; Pindell, 1985), evidenced in the sandy lithology of the Río Negro Formation. Subsequently, the subsidence stabilized and the Cogollo group (Apón, Lisure, Maraca successions) was deposited in an extensive epicontinental sea. During the Cenomanian-Santonian the maximum marine cover was deposited, forming the anoxic-euxinic environments that gave rise to the deposition of the Capacho and La Luna formations. After maximum transgression, a regressive cycle began that conserved the marine environment and is evidenced by the glauconitic and phosphatic layers of the Tres Esquinas Member in the La Luna Formation. Finally, the shales of the Colón Formation were deposited, which change transitionally to the Mito Juan Formation (Fig. 2A; González de Juana et al., 1980; Parnaud et al., 1995)

According to Villamil and Pindell (1998), the middle–late Albian stratigraphic record west of Venezuela shows an abrupt transgression generating regional condensed sediments and the deposition of significant intervals of source rocks. The upper condensed transgressive systems tract (late Albian) is characterized by the deposition of the La Grita Member facies in the Capacho Formation in western Venezuela, as shown in terms of sequence stratigraphy in Figure 2D. This deposition cycle began with basal transgressive sand from the early to late Albian, corresponding to the Aguardiente Formation (sandstone and silstone). This formation represents a tidal-dominated deltaic system (Renz, 1959; Maceralli, 1988) and is stratigraphically

128 a highstand systems tract (HST). With the progressive increase in sea level, the La

129 Grita Member represents a transgressive systems tract (TST) characterized by anoxic

130 facies in which the unit top represents the maximum flooding surface (MFS)

131 (Macellari, 1988; Méndez et al., 2015). The final phase of the cycle is represented by

132 shales at the base of the Seboruco Member (Renz, 1959). Towards the southeast of the

133 basin, the La Grita Member changes transitionally to the basal shales of the

134 Ecandalosa Formation, while in the northeast the member passes transitionally to the

135 base of the La Luna Formation (Renz, 1959; Fig. 2B)

136 The La Grita Member is 5–10 m thick, with a lithology very similar to the

137 calcareous shales facies of the La Luna Formation, which are dense black limestones

138 finely intercalated with black to dark-grey calcareous shales and calcareous

139 concretions. Overall, the petrographic study by Rodríguez (1989) classifies these

140 rocks as mudstone and wackestone (Dunham, 1962). In more detail, the limestones

141 are typified by high contents in organic matter, pyrite, and a dark micritic matrix that

142 is partially recrystallized (microspar-pseudospar). The matrix contains microfossils

143 (mainly planktonic foraminifera), quartz, and accessory minerals such as fluorapatite,

144 glauconite, muscovite, and zircon.

145 **2.2. Occurrence of Cretaceous oceanic anoxic events in western Venezuela**

146 The conditions of anoxia and the intervals of high content of organic matter

147 recorded in western Venezuela during the Cretaceous have been correlated

148 chronostratigraphically to different OAEs represented in the Aptian (OAE-1a and 1b;

149 Baquero et al., 2008; Mendez et al., 2008; Mendez-Dot et al., 2015), Cenomanian-

150 Turonian (OAE-2; Pérez-Infante et al., 1996; Erlich et al., 1999a), and Coniacian-

151 Santonian (regional OAE-3; Rey et al., 2004; Machado et al., 2016).

152   Baquero et al. (2008) have described two major transgressive events in the Apón

153 Formation, which correspond to the Machiques Member (OAE-1a; early Aptian) and

154 the top of the Piché Member (OAE-1b; late Aptian). Both levels have an average TOC

155 between 2-3%, with occasional values between 5-6% (Méndez et al., 2008). The

156 Machiques Member is a pelagic limestone originated on the shallow platform,

157 interspersed with some transgressive events that moved from pelagic to the shallow-

158 water platform facies (Méndez et al., 2008). The Piché Member is a stratigraphic

159 transgressive and regressive sequence. Towards the top of this member the anoxic

160 environments were transferred to the internal platform by marine transgressions as

161 happened in the Machiques Member. Based on the stratigraphic distributions of trace

162 metals (Mo, V, Fe) and sulfur in the Aptian-Albian interval of the Machiques

163 Member, Alberdi and Tocco (1999) suggest deposition conditions with cyclic pattern

164 of oxic-anoxic episodes and the deposit of a mixture of marine and terrestrial organic

165 matter.

166   On the other hand, the La Luna Formation represents the most important source

167 rock of the region with average TOC values of ~6% (Talukdar et al., 1985; Talukdar

168 and Marcano, 1994). The highest TOC intervals occur across the Cenomanian-

169 Turonian, Coniacian-early Santonian, and rapidly decrease during the late Santonian

170 (Erlich et al., 1999b). In the La Luna Formation the accumulation of organic matter

171 began in the middle to late Cenomanian in an open marine environment, with depths

172 of a few hundred meters and very low clastic contribution. Pérez-Infante et al. (1996)

173 suggest that this black shale deposition from the La Luna Formation was a local

174 response to the conjunction of an increase in sea level and the presence of upwelling

175 currents. The Cenomanian/Turonian boundary event is marked in the middle section

176 of the La Luna Formation with a positive change in $\delta^{13}C_{org}$ values, which does not

respond to local changes in bioproductivity or in the intensification of anoxic conditions (Pérez-Infante et al. al., 1996), therefore possibly marks the global isotopic change associated with OAE-2. Conversely, $\delta^{13}C_{carb}$ values in Coniacian-Santonian interval not fit with the significant carbon isotope excursion as expected for the OAE and support the hypothesis that OAE-3 is not a global but a regional anoxic event with restricted areal distribution of organic carbon burial in the low-to-mid latitude (e.g., Wagreich, 2012; Machado et al., 2016).

Overall, the Maracaibo Basin represents an interesting conjunction that involves hydrocarbon generating levels and levels with conventional porosities and fractures that act as flow units and reservoir of hydrocarbons, forming a petroleum system of economic importance (e.g., Talukdar et al., 1985; Talukdar and Marcano, 1994; Méndez et al., 2015).

3. Material and methods

3.1 Sampling

The stratigraphic section was sampled from an outcrop on the Guaruríes River (8°25'08''N; 71°46'31''W; 5.3 km SW of the village of Zea) in the Tovar district, state of Mérida (Fig. 2B). The La Grita Member is approximately 7 m thick in this outcrop. A total of 33 samples were collected every 25 cm in the La Grita Member interval and every 100 cm in the underlying units (Maraca Formation to the Aguardiente Formation) and overlying unit (Seboruco Member) (Fig. 3). An aliquot (~50–100 g) of each sample was crushed and ground with a tungsten carbide Shatterbox mill. Later, each sample was sieved through a 100-mesh screen in order to homogenize the degree of pulverization.

3.2 Biostratigraphic analysis

For the biostratigraphic analysis, thin sections were prepared from 14 samples chosen considering lithological changes, mineral composition, and stratigraphic level (Fig. 5). Due to the high degree of diagenesis, the foraminifera were classified by shape, chamber arrangement, and size. To determine biostratigraphic Zones and age, we used the Zone scheme of Sliter (1989) and Premoli Silva and Sliter (1995). The microfossils preserved in rocks thus identified provided data on relative age, sedimentary environment, and the paleo-ecological conditions of deposition of the La Grita Member.

3.3 Analytical procedures

3.3.1. Stable isotope analysis (carbon and oxygen)

Bulk carbonate carbon ($\delta^{13}C_{Carb}$) and oxygen ($\delta^{18}O_{carb}$) isotope analyses were carried out on powdered bulk-rock samples using a dual-inlet stable isotope mass spectrometer system (Thermo Fisher Scientific Delta Plus V). Organic carbon isotopes ($\delta^{13}C_{org}$) were also measured on the bulk organic fraction of decarbonated (6M HCl treatment) samples using a Flash EA 1112 automatic elemental analyser connected to a Thermo Fisher Scientific Delta Plus V isotope ratio mass spectrometer via a Conflo III interface. The stable carbon and oxygen isotope ratios are reported in the delta notation as the per mil (‰) deviation relative to the Vienna Pee Dee Belemnite (VPDB) standard. Analytical precision and accuracy were determined by replicate analyses of samples and replicate analyses of in-house standards (CAL-INT, acetanilide, and sucrose; Appendix A.1 and A.2), calibrated with international standards (NBS16, NBS17, NBS18, NBS19, NBS22, USG24; Appendix A.3) and were better than ±0.2‰ (1σ) for carbon and ±0.5‰ (1σ) for oxygen.

3.3.2 Total organic carbon, total sulfur and pyrite analyses

Total organic carbon (TOC) and total sulfur (S_t) was determined on the carbonate-free fraction (cff) using a LECO CS-600 elemental analyzer. The decarbonated fraction was obtained by a 6M HCl treatment. TOC contents were recalculated to the original sample mass.

The pyrite content was studied by X-ray diffraction (XRD). The random powder samples were side-loaded into the holders and analysed on a PANalytical X'Pert Powder diffractometer. This instrument is fitted with a copper tube (Cu K-alpha = 1.54178 Å), operating at 45 kV and 40 mA and a post-diffraction graphite monochromator. Samples were scanned from 5° to 65° two-theta in steps of 0.020° two-theta and a counting time of 2 seconds per step. For the semi-quantification of the major mineralogical components, bulk sediment XRD scans were processed in the software package X'Pert High-Score Plus (PANalytical) using the Rietveld full-pattern fitting method (e.g., Young, 1993; Grunsky et al., 2013). This method permits the semi-quantification of whole-sediment mineralogy with a precision of 5% for non-phyllosilicates minerals. In this article, only the pyrite content is used.

3.3.3 Analysis of major, minor, and trace elements

A total of 11 elements (Al, Si, P, K, Ca, Ti, Mn, Fe, V, Sr, Zr) were analyzed by energy dispersive X-ray fluorescence (EDXRF) spectrometry using a PANalytical Epsilon 3-XL. Before EDXRF analysis, loss on ignition (LOI) was determined gravimetrically by heating to 950°C for two hours. Subsequently, samples were treated by borate fusion in an automated fusion furnace (CLAISSE® M4 Fluxer). Samples weighing ~0.6 g were mixed with ~6 g of lithium borate flux (CLAISSE, pure, 49.75% Li2B4O7, 49.75% LiBO2, 0.5% LiBr). The mixtures were melted in Pt-Au crucibles (95% Pt, 5% Au), and after fusion the melts were cast to flat disks

252 (diameter: 32 mm; height: 3 mm) in Pt-Au moulds. Acquired XRF spectra were

253 processed with the standardless Omnian software package (PANalytical). The

254 resulting data are expressed as weight percent (wt.% ; Al, Si, P, K, Ca, Ti, Mn, Fe)

255 and micrograms per gram (µg/g; V, Sr, Zr). Procedural blanks always accounted for

256 less than 1% of the lowest concentration measured in the sediment samples.

257 Analytical accuracy and precision were found to be better than 1–5% for major

258 elements and 5–10% for the other elements, as checked by an international standard

259 (USGS SDC-1; Appendix B.1) and analysis of replicate samples.

260 Further major and trace elements (e.g., Na, Sc, Cr, Ni, Cu, Zn, Rb, Nb, Mo, Hf, Th,

261 U) were analyzed by laser ablation inductively coupled plasma mass spectrometry

262 (LA-ICP-MS) as described in previous studies (e.g., Jackson, 2001, 2008; Leite et al.,

263 2011; Wegner et al., 2015). A NewWave UP213 196 nm excimer ablation system

264 interfaced to an inductively coupled plasma-quadrupole mass spectrometer (ICP-QMS

265 Agilent 7500c) was used for the ablation of the lithium tetraborate discs previously

266 analyzed by EDXRF. Operating conditions of the ablation system included a 10 Hz

267 repetition rate, 100 µm spot size, 5µm.s^{-1} scanning velocity, and circa 10 J.cm^{-2} on-

268 sample energy density. Helium was used as a carrier gas; the make-up gas argon was

269 admixed after the ablation cell and the aerosol carried to the ICP-MS. The acquisition

270 times for the background and the ablation interval were circa 170 and 370 s,

271 respectively. Dwell times per isotope ranged from 10 ms for major elements to 30 ms

272 for trace, and peak-hopping mode was employed. The ICP-MS system was tuned

273 using a NIST SRM 612 synthetic glass standard to ensure robust plasma conditions

274 while maximizing the signal to background intensity ratio and retaining low oxide-

275 production levels (<0.5% ThO). Bracketed external standardization used NIST SRM

276 612 glass. Calcium contents obtained by EDXRF were used for internal

277   standardization. Data reduction for concentration and limit of detection calculations

278   was undertaken offline using the software LAMTRACE (Jackson, 2008). Procedural

279   blanks always accounted for less than 1% of the lowest concentration measured in the

280   samples. The analytical accuracy and precision were found to be better than 4% for all

281   elements, as checked by NIST SRM 612 (Appendix B.2) standard and analysis of

282   replicate samples.

283   The chemical index of alteration (CIA), corrected for the carbonate and phosphate

284   contents (e.g., McLennan et al., 1993; Fedo et al., 1995), was used to evaluate the

285   degree of chemical weathering in the source areas. This index was calculated as

286   follow: $CIA= 100 \times [Al_2O_3/(Al_2O_3+CaO^*+Na_2O+K_2O)]$ in molar proportions (Nesbitt

287   and Young, 1982). Likewise, to compare the relative enrichment of redox-sensitive

288   elements (RSTE: V, Ni, Cr, Zn, Mo, U), we calculated enrichment factors (EF) by

289   comparing Al-normalized metal concentrations to those of average shale (Wedepohl,

290   1991): $X_{EF} = [(X/Al)_{sample}/(X/Al)_{average\ shale}]$. In practical terms, EF > 3 represents a

291   detectable authigenic enrichment of an element over average shale concentrations,

292   whereas EF > 10 represents a moderate to strong degree of authigenic enrichment

293   (e.g., Tribovillard et al., 2006).

294   A compositional Q-mode cluster analysis (e.g., Egozcue and Pawlowsky-Glahn,

295   2005; Pawlowsky-Glahn and Egozcue, 2011; Montero-Serrano et al., 2015) was

296   performed on the elemental geochemical dataset with the goal of finding elemental

297   associations with similar relative variation patterns that may be interpreted from a

298   palaeoenvironmental standpoint (e.g., Jaminski et al., 1998; Hoffman et al., 1998;

299   Reátegui et al., 2005; Montero-Serrano et al., 2010a, 2015). This analysis was carried

300   out using a log-ratio approach (Egozcue and Pawlowsky-Glahn 2005). Likewise, as a

301   measure of dissimilarity we use the variation array, and as a clustering criterion the

302 Ward method. All statistical calculations were conducted with "R" software using the

303 packages "StatDA" (Reimann et al., 2008) and "compositions" (van den Boogaart and

304 Tolosana-Delgado, 2008).

305 In addition, in order to infer palaeoenvironmental changes (e.g., weathering,

306 sediment input, redox conditions) during OAE-1d, the stratigraphic distribution of the

307 elemental geochemical associations obtained by the compositional Q-mode cluster

308 analysis were represented as elemental balances **(1)**. Elemental balances are log-

309 contrasts resulting from a log-ratio of two geometric means of two non-overlapping

310 elemental groups (Egozcue and Pawlowsky-Glahn, 2005). The general expression of

311 an elemental balance is:

312 $$b = [\sqrt{(r \times s \,/\, r + s)}] \times Log[gm(A)/gm(B)] \qquad \textbf{(1)}$$

313 where A, B are two non-overlapping elemental groups of a complete composition x of

314 D elements (e.g., Ti, Zr, Si, K, Al,…, x_D), r and s (r + s ≤ D) are the number of

315 elements in A, B respectively, and gm(.) denotes the geometric mean of the elemental

316 groups A and B.

317 All analytical data presented are available electronically in the Supplementary

318 Appendix B.1 and B.2.

319

4. Results

4.1 Biostratigraphy

322 Diversity is relatively low in the planktonic foraminifer assemblage in the La Grita

323 Member, and it is dominated by the following species: *Hedbergella (delrioensis,*

324 *planispira, rischi, simplex), Globigerinelloides (bentonenis, ultramicra, caseyi),*

325 *Ticinella (roberti, primula, raynaudi), Heterohelix (morenami, reussi)* and, to a lesser

326 extent, *Planomalina (buxtorfi), Whiteinella (baltica),* and *Rotalipora (ticinensis)* (Fig.

327   4). Note that the biostratigraphic Zones have certain limitations since the total

328   foraminifer assemblage was not counted. The different biostratigraphic Zones

329   characterizing the La Grita Member are described below (Fig. 5):

330   -   *Rotalipora appenninica* Zone (late Albian). Covers the interval of samples

331   ZEARG-185 (based on the La Grita Member) to ZEARG-95 (top of La Grita

332   Member). This interval is characterized by the presence of the species *Ticinella*

333   *primula*, *Ticinella roberti*, *Ticinella raynaudi*, *Biticinella breggiensis*, *Hedbergella*

334   *rischi*, and *Planomalina* cf *praebuxtorfi*, with *Rotalipora* cf *ticinensis* identified

335   towards the base of the sequence. Towards the top of the Zone, *Heterohelix moremani*

336   was identified.

337   -   *Rotalipora brotzeni-Rotalipora reicheli* Zone (early Cenomanian). The

338   microphotographs show no evidence of an early Cenomanian age from the *Rotalipora*

339   *brotzeni* Zone to the *Rotalipora reicheli* Zone. Above sample ZEARG-95 (boundary

340   of previous Zone), a thin section analysis on the sample ZEARG-90 revealed the

341   species *Hedbergella planispira*. However, this species' wide stratigraphic range does

342   not aid in constraining the age for this interval.

343   -   *Rotalipora cushmani* Zone (late Cenomanian). At the top of this sequence

344   (from sample ZEARG-85 to ZEARG-05), the foraminifer assemblage is characterized

345   mainly by species from the genera *Hedbergella*, *Globigerinelloides*, and *Heterohelix*.

346   The first occurrence of *Heterohelix reussi* in sample ZEARG-85 and the presence of

347   *Whiteinella* cf *baltica* in sample ZEARG-65 identify it as a *Rotalipora cushmani*

348   Zone.

349

350   **4.2. Stable isotopes ($\delta^{13}C_{Carb}$, $\delta^{18}O_{Carb}$, $\delta^{13}C_{org}$), total organic carbon and pyrite**

351   The vertical distributions of $\delta^{13}C_{carb}$, $\delta^{18}O_{carb,}$ and $\delta^{13}C_{org}$ for the La Grita Member

352   are presented in Figure 6A-C. Generally, $\delta^{13}C_{carb}$ trends towards more positive values

353   upwards in the stratigraphic column. At the boundary between the Aguardiente

354   Formation and the La Grita Member, carbon isotope values of carbonate show a

355   pronounced positive carbon isotope excursion (or CIE) of ~4‰. Within the

356   *Rotalipora appenninica* Zone, corresponding to OAE-1d the magnitude of this

357   positive CIE is around 1‰ (Fig. 6A). Within this $\delta^{13}C$ anomaly, four cyclical

358   variations (~2.6‰ in magnitude) are observed. In contrast, the $\delta^{13}C_{carb}$ values in the

359   Seboruco Member shows few variations, with average values of ~-1‰.

360   The $\delta^{18}O_{carb}$ values in the section corresponding to the Aguardiente Formation and

361   Maraca show a shift of ~8.9‰ towards more positive values of $\delta^{18}O$ (from -14.1‰ to

362   -5.2‰; Fig. 6B). In the interval corresponding to the La Grita Member, the $\delta^{18}O_{carb}$

363   profile also shows cyclical variations ranging from -12.7‰ to -10.2‰, which are

364   significantly high values (over -5‰). The cyclical variations noted in the $\delta^{18}O_{carb}$

365   profile could be related to the cyclical trend observed for $\delta^{13}C_{carb}$. In contrast, the

366     $\delta^{18}O_{carb}$ profile in the Seboruco Member shows few variations, with average values of

367   ~ -10.6‰.

368   Furthermore, carbon isotope values of bulk organic matter ($\delta^{13}C_{org}$; Fig. 6C) show

369   relatively higher values in the Aguardiente and Maraca successions (-27 to 26‰)

370   compared to the La Grita and Seboruco members (~ -28‰). TOC concentrations are

371   low in the Aguardiente and Maraca formations (<1%) compared to the La Grita

372   Member and Seboruco (5-10%; Fig. 6D), while pyrite shows a slight increase during

373   the positive CIE with two marked increases (up to 4%; Fig. 8C) recorded in the base

374   of the La Grita Member.

375 **4.4 Elemental geochemistry**

376   The compositional Q-mode cluster analysis of the La Grita Member revealed four

377   major elemental geochemical associations (Fig. 7):

378   Redox (V, Zn, U, Mo, Cr, Ni) and organic matter-sulphide (TOC, S) groups:

379   consists of elements that tend to be less soluble or sulfide forming under reducing

380   conditions. Indeed, these elements are commonly associated with the organic matter

381   and the authigenic sulfides fraction, whose accumulation is largely controlled by the

382   oxic-anoxic conditions of the sedimentary environment (e.g., Jaminski et al., 1998;

383   Algeo and Maynard, 2004; Brumsack, 2006; Tribovillard et al., 2006; Calvert and

384   Pedersen, 2007). Among these elements, and U–Mo covariation are reputed

385   paleoredox-indices (e.g., Jones and Manning, 1994; Algeo and Maynard, 2004;

386   Tribovillard et al., 2006; Algeo and Ingall, 2007).

387   Siliciclastics group (Al, Si, Ti, K, Sc, Rb, Nb, Hf, Zr): consists of elements

388   associated with clay and silt particles, mainly as chemical constituents of the detrital

389   mineral grains (e.g., phyllosilicates, quartz, plagioclases, K-feldspar) or adsorbed on

390   their surface (e.g., Calvert and Pedersen, 2007; Montero-Serrano et al., 2010, 2015).

391   Thus, the variability of riverine inputs related to continental climate fluctuations and

392   the subsequent hydraulic partitioning of the sediments mostly control the distribution

393   and accumulation of these elements. Among these detrital elements, the Rb/Sr, Ti/Al

394   ratios may be used to evaluate detrital fluxes and changes in chemical weathering at

395   the source areas (Li et al., 2003; Croudace and Rothwell, 2015).

396   Carbonates group (Ca, Sr): consists of elements related with calcium carbonate

397   (mainly calcite) associated with calcareous cement as well as planktonic fauna

398   (including *Hedbergellas*, *Globigerinelloides*, *Ticinellas*, *Planomalinas*, *Whiteinellas*,

399   and *Rotaliporas*), which agrees with the petrographic interpretations. The carbonate-

400   associated elements correlate negatively with the other two elemental associations,

401   and thus likely represent a dilution fraction.

402   Fe-Mn oxyhydroxides group (Mn-Fe-P-Cu-Na): consists of elements mainly found

403   in the structure of Fe-Mn-oxyhydroxides. Due to the reactive nature of Fe-Mn-

404   oxyhydroxides, some other elements such as P and Cu can be sorbed on the surface of

405   this mineral phase (Delaney, 1998; Mort et al., 2007). In addition, P can also be

406   associated with organic matter, detrital material, and authigenic minerals such as

407   colophane (Mort et al., 2007) as well as skeletal remains. In fact, abundant brachiopod

408   shells and fish bones were identified in a previous petrographic study of the La Grita

409   Member (Rodríguez, 1989).

410   Based on these geochemical associations, elemental balances [$b_{(siliciclastic/carbonate)}$

411   and $b_{(redox/carbonate)}$] are performed. The vertical distribution of the siliciclastic balance

412   (Al, Si, Ti, K, Sc, Rb, Nb, Hf, Zr) and redox balance (V, Zn, U, Mo, Cr, Ni) show

413   similar patterns (Figs. 7A,D; 8G; 11A), with minimum values recorded in the

414   Aguardiente and Seboruco members and maximum values in the *Rotalipora*

415   *appenninica* Zone. Similary, detrital element ratios (Rb/Sr, Ti/Al and CIA index) also

416   increase in the *Rotalipora appenninica* Zone.

417   The stratigraphic distribution of the RSTE enrichment factors (U, V, Mo, Cr, Ni,

418   and Zn) is show in Figure 8A-B. In general, these elements record heavy enrichment

419   only at the base and top of the La Grita Member, with values ranging between 10 to

420   100 (some up to 500) times in comparison to average shale.

421

5. Discussion

5.1 Biostratigraphy and age of the La Grita Member

424   The studied foraminifer assemblages show that the La Grita Member is located in

425   the *Rotalipora apenninica* Zone, which is indicative of a range of ages between

426   100.1–98.9 Ma (Premoli Silva and Verga, 2004). In addition, the absence of marker

427   foraminifer species from the early Cenomanian (zones *Rotalipora brotzeni* and

428   *Rotalipora reicheli*) suggest this time interval is likely condensed in a limestone bed

429   at a stratigraphic depth of 8.25 m (~25 cm thick). However, in agreement with several

430   sedimentological studies from western Venezuela (Canache et al., 1994; Crespo et al.,

431   1999; Truskowski, 2006), we attribute this to the presence of a stratigraphic gap or

432   hiatus covering the early Cenomanian interval. Indeed, Canache et al. (1994) suggest

433   this hiatus is related to the collision of the Pacific volcanic arc with the South

434   American Plate. As a result of this collision, a foreland developed west of the Sierra

435   de Perijá and a forebulge appeared in the areas of Perijá and Lake Maracaibo. The

436   forebulge became the raised Maracaibo basin, which restricted deposition and

437   promoted erosion of the upper part of the K2 sequence (including the Aguardiente,

438   Maraca, and lower Capacho sucessions, Fig. 2C) during the early Cenomanian.

439   Therefore, the early Cenomanian beds of the La Grita Member were likely impacted

440   by submarine erosion and/or non-deposition, thereby erasing the sedimentary record

441   of this interval. Subsequently, renewed transgression rapidly flooded the area as a

442   result of renewed compression and regional flexural downwarping in the Maracaibo

443   basin (Canache et al., 1994).

444

445   **5.2 Effect of diagenesis on stable isotope signatures**

446   The usefulness of the isotope record of carbon and oxygen as paleoenvironmental

447   proxies depends on the degree of post-depositional diagenetic alteration undergone by

448   rocks (Algeo et al., 1992; Marshall, 1992). Indeed, the original stable isotope values

449   of carbonate sediment are susceptible to open-system diagenesis because of influxing

450   meteoric or burial fluids and the cementation of primary porosity (Immenhauser et al.,

451   2001; Moore, 2001; Phelps et al., 2015). Oxygen isotope values are more susceptible

452   to diagenetic alteration than carbon isotopes during burial diagenesis since oxygen

453   isotopes display significant fractioning with variations in temperature (Anderson and

454   Arthur, 1983; Marshall, 1992).

455   The $\delta^{13}C_{carb}$-$\delta^{18}O_{carb}$ crossplots have been succesfully used to assess the degree of

456   diagenetic alteration of the carbonate samples (e.g., Anderson and Arthur, 1983;

457   Marshal, 1992; Schobben et al., 2016). Figure 9 show that most of the samples have

458   late diagenetic alteration (Schobben et al., 2016). Late diagenesis occurs over the

459   period of deposition, when sediments are only lightly compacted, corresponding to

460   burial processes that act at depth over long geological periods (Flügel, 2004). This

461   diagram illustrates how the burial process acts as a closed system in which variations

462   only occur on the $\delta^{18}O_{carb}$ axis, since this variable is the most sensitive to the

463   temperature changes that occur with burial. So the cement precipitated during burial

464   (enriched in light isotopes) have greater influences on the change in oxygen isotope

465   values, whereas as the $\delta^{13}C_{carb}$ values remain practically constant (Marshall, 1992;

466   Bornemann et al., 2005). Therefore, we hypothesized that the observed $\delta^{18}O_{carb}$ pattern

467   (higher values in limestone beds and lower in marls; Fig. 6B) most likely reflects the

468   timing of burial diagenesis rather than changes in the palaeoceanic isotope signal

469   (such as salinity and temperature). Indeed, during burial diagenesis, limestone cement

470   forms early, at shallow depths and lower burial temperatures, and thus acquires higher

471   $\delta^{18}O$ values (~ -7 to 8‰) compared to marls (~ -11‰), which cement later (e.g.,

472   Algeo et al., 1992; Schrag et al., 1995; Rosales et al., 2004). In this context and

473　despite the diagenetic alteration of the $\delta^{18}O_{carb}$ signature, we can assume that the

474　$\delta^{13}C_{carb}$ values probably represent a primary environmental signal.

475

476　**5.3 The OAE-1d expression in the La Grita Member**

477　Bréheret (1988) provided one of the first descriptions of OAE-1d in a geochemical

478　study of episodes of organic-rich sedimentation from the Vocontian Basin (SE

479　France), where the upper Albian contains a certain number of small beds

480　(concentrated in a 10-meter-thick level) with a TOC% of 1–2%, termed the

481　Breistroffer Level. Beds equivalent to OAE-1d have been described in detail from SE

482　France (Breistroffer Level; Bréheret, 1988; Giraud et al., 2003; Bornemann et al.,

483　2005), Romania (Melinte-Dobrinescu et al., 2015), Italy (Erbacher et al., 1996;

484　Giorgioni et al., 2012; Gambacorta et al., 2015; 2016), Tunisia (Ben Fadhel et al.,

485　2011), the United States (Robinson et al., 2008; Scott et al., 2013), and the Atlantic

486　Ocean (Mazagan Plateau, Nederbragt et al., 2001; Leckie et al., 2002; Blake Nose

487　Plateau, Wilson and Norris, 2001; Watkins et al., 2005; Fig. 1). This widespread

488　distribution of carbon-enriched facies during the OAE-1d suggests a potentially global

489　perturbation of the carbon cycle.

490　Based on biostratigraphy (*Rotalipora apenninica* Zone), carbon-isotope

491　chemostratigraphic and higher TOC values, the OAE-1d positive CIE has been

492　unambiguously identified in the La Grita Member (Fig. 6A). The increase in the TOC

493　contents and the positive $\delta^{13}C_{carb}$ excursion are characteristic of different OAEs,

494　including OAE-1d (Schlanger and Jenkyns, 1976; Jenkyns, 2010). The selective

495　withdrawal of organic matter enriched in ^{12}C and its limited recycling causes the CO_2

496　in the ocean and atmospheric reservoirs to become enriched in ^{13}C during OAEs,

497　leading a positive $\delta^{13}C$ excursion (Nemoto and Hasegawa, 2011). The positive $\delta^{13}C_{carb}$

498   anomaly observed at the onset of the OAE-1d in the La Grita Member is comparable

499   to the OAE-1d isotope expressions recorded in the Atlantic Ocean (Wilson and

500   Norris, 2001; Scott et al., 2013), in western Tethys (Bornemann et al., 2005; Gale et

501   al., 2011; Giorgioni et al., 2012), and in western Pacific Ocean (Navarro-Ramirez et

502   al., 2015; Fig. 10).

503   Pronounced $\delta^{13}C_{carb}$ cycles (~0.5 to 1%) observed in the calcareous shales,

504   limestone and shale from the La Grita Member (Fig. 6A-B) are the typical lithological

505   expression of the late Albian OAE-1d (Girogioni et al., 2012). The stratigraphic

506   distribution of $\delta^{13}C_{carb}$ in the *Rotalipora appenninica* Zone show a cyclical pattern

507   similar to those reported from the Umbria-Marche Basin (Figs. 6A,10). Giorgioni et

508   al. (2012) and Yao et al. (2018) suggest that the fluctuating monsoonal regime,

509   coupled with an unstable oceanic structure, made the oceanic carbon reservoir

510   sensitive to orbital variations during the mid-Cretaceous. However, a more detailed

511   cyclostratigraphic study is needed to elucidate these orbital cycles in the La Grita

512   Member.

513   Furthermore, the $\delta^{13}C_{org}$ values mostly lie between -28 and -26‰ throughout the

514   La Grita Member (Fig. 6C). These $\delta^{13}C_{org}$ values are typical of marine organic matter

515   accumulated during the mid-Cretaceous (Dean et al., 1986). Consequently, the change

516   in the $\delta^{13}C_{org}$ isotopic composition between the Aguardiente Formation and the La

517   Grita Member could correspond to a change in the source of the organic matter. Such

518   a change suggests a greater influence of terrestrial organic matter in the Aguardiente

519   Formation and a greater supply of marine organic matter in the La Grita Member as

520   transgression proceeded. Dean et al. (1986) attribute this difference to a greater

521   availability of dissolved CO_2 for marine algae because of the higher pCO_2 in the mid-

522   Cretaceous atmosphere.

523

5.4 Paleoenvironmental conditions during the OAE-1d

5.4.1 Continental weathering

Changes in the weathering at the source areas and clastic influx that prevailed during deposition of the La Grita Member are inferred using the siliciclastic balance, Rb/Sr and Ti/Al ratios and CIA index (Li et al., 2003; Croudace and Rothwell, 2015; Nesbitt and Young, 1982). Higher values in these detrital proxies could be interpreted as: (1) heavier rainfall and enhanced continental weathering and runoff, and/or as (2) lowered carbonate production in surface water. However, we must reject this last hypothesis because the vertical distribution of Ca shows higher values (up to 60%) during the OAE-1d relative to the rest of the succession. Therefore, in the La Grita Member, the meaningful increase in the siliciclastic balance, Rb/Sr, Ti/Al ratios and CIA index observed during the OAE-1d (*Rotalipora appenninica* Zone; Fig. 11A-D) more likely suggests an enhanced continental weathering rates and detrital discharge deriving from an accelerated hydrological cycle. Some authors (e.g., Wilson and Norris, 2001; Leckie et al., 2002; Gambacorta et al., 2015; Navarro-Ramírez et al., 2017) have concluded that the elevated pCO2 levels and greenhouse climate prevailing during the OAE-1d induced an acceleration of the hydrologic cycle and an increase in continental weathering rates. The elevated pCO2 levels were caused by the release of CO_2 associated with the volcanic eruption of Hess Rise in the northern Pacific Ocean (Eldholm and Coffin, 2000; Boudgher-Fadel, 2015) and/or to the eruption of the central portion of the Kerguelen Plateau LIP (Richey et al., 2018; Fig. 1). These results are in good agreement with interpretations by Navarro-Ramírez et al. (2017) that suggest also higher weathering rates in the Brazilian massif during the mid-Cretaceous. Furthermore, the higher hydrolysing conditions recorded in the La

548 Grita Member may also favoured higher nutrient fluxes into the basins, ultimately

549 boosting primary productivity and the development of oxygen-depleted conditions

550 (Föllmi et al., 1994; Weissert et al., 1998; Jenkyns, 2010; Fantasia et al., 2018).

551 On the other hand, the vertical distribution of most of the detrital elements also

552 shows a cyclical variability (Fig. 7D). As discussed before, this variability may reflect

553 fluctuations in the rivers discharges possibly driven by longer-term (i.e., orbital) shifts

554 of the mean annual position of the Intertropical Convergence Zone (ITCZ), which

555 connects the large-scale precipitation and wind field patterns of the Hadley cells

556 (Borneman et al., 2005; Hofmann and Wagner, 2011; Giorgioni et al., 2012;

557 Hasegawa et al., 2012). Borneman et al. (2005) and Giorgioni et al. (2012) suggest

558 that long eccentricity cycles likely induced an exceptionally strong seasonal contrast,

559 at least in western Tethys, during the OAE-1d. These results support the idea that the

560 orbital forcing likely also modulated the equatorial monsoonal activity during the

561 OAE-1d (Borneman et al., 2005; Hofmann and Wagner, 2011; Giorgioni et al., 2012).

562 *5.4.2 Redox conditions*

563 The redox conditions that prevailed during the deposition of the La Grita Member

564 are investigated using several proxies (Figs. 8 and 12): RSTE enrichment factors (U,

565 V, Mo, Cr, Ni, Zn), pyrite content, total sulfur, redox balance (V, Zn, U, Mo, Cr, Ni),

566 the ternary diagram TOC-S-Fe and U–Mo and Mo-TOC co-variation patterns.

567 Stratigraphic variations in the RSTE enrichment factors, pyrite content, total sulfur

568 and the redox balance show similar trends that suggest prevailing oxic conditions in

569 the Aguardiente and Maraca formations and anoxic-euxinic conditions in the La Grita

570 and Seboruco members (Fig. 8A-G). These results are in agreement with the TOC–S–

571 Fe relationship, which is commonly used to evaluate paleo-oxygenation conditions in

572 the sedimentary environment (Dean and Arthur, 1989; Rimmer et al., 2004; Montero-

573   Serrano et al., 2010b; Fig. 12A). The samples plot along a line of constant S/Fe ratio,

574   as in the present study (La Grita and Seboruco members), indicates anoxic deposition

575   conditions (similar conditions to the deposit of the La Luna Formation; Lo Mónaco et

576   al., 2002) and, the limiting factor in pyrite formation was not TOC content but the

577   quantity of detrital reactive Fe present (Raiswell and Berner, 1985; Arthur and

578   Sageman, 1994). However, at the boundary between the La Grita and Seboruco

579   members, the stratigraphic variations show that the anoxic conditions are interrupted

580   at 8.25 m by an abrupt change to dysoxic conditions. Based on the biostratigraphic

581   information discussed above, we hypothesize this change could be related to the

582   hiatus (Figs. 5 and 8H). After this episode, anoxic conditions were gradually re-

583   established, apparently due to a rapid basin subsidence (Canache et al., 1994).

584   Although the TOC content indicates prevailing anoxic conditions throughout the

585   entire depositional period of the La Grita Member, the RSTE only show two episodes

586   of strong enrichment (EF>10), at 3.50 m and at 8.25 m (Fig. 8A-B). This trend in the

587   RSTE can be interpreted as the cause of a basin reservoir effect (e.g., Algeo and

588   Lyons, 2006; Tribovillard et al., 2008; Algeo and Rowe, 2012) described for several

589   modern anoxic marine environments, in which a strong pycnocline or a restriction of

590   the basin induces dramatic isolation of the deep-water mass. In this environment, the

591   inventory of dissolved trace metals could become depleted as the sink flux of trace

592   metals to the sediments exceeds the input associated with deep-water renewal

593   (Tribovillard et al., 2008).

594   In addition, the patterns of U-Mo covariations coupled with trace-metal

595   concentrations versus TOC diagrams provide suitable information on the evolution of

596   paleoenvironmental marine systems, and in particular on water-mass restriction

597   (Algeo and Lyons, 2006; McArthur et al., 2008; Algeo and Tribovillard, 2009; Algeo

and Rowe, 2012; Tribovillard et al., 2012). This is due to the different geochemical behaviour of U and Mo: (1) the uptake of authigenic U by marine sediments begins at the Fe(II)–Fe(III) redox boundary (i.e., suboxic conditions), whereas authigenic Mo enrichment requires the presence of H_2S (i.e., euxinic conditions), and (2) the transfer of aqueous Mo to the sediment may be enhanced through particulate shuttles, whereas aqueous U is unaffected by this process (Tribovillard et al., 2012).

The covariation in the EF of U-Mo for the corresponding samples of the La Grita Member is illustrated in Figure 12B. The distribution of the samples exhibits greater enrichment of Mo relative to U ($[Mo/U]_{agua\ de\ mar}$ 1-3 and >3), reflecting the operation of a metal-oxyhydroxide particulate shuttle within the water column, over a range of redox conditions, predominantly anoxic to probably euxinic (equal increases in Mo and U; Algeo and Tribovillard, 2009; Tribovillard et al., 2012). This is typically the feature observed in ancient and modern weakly restricted basins (e.g., La Luna Formation in Maracaibo Basin and Cariaco Basin respectively; Algeo and Tribovillard, 2009; Tribovillard et al., 2012). These interpretations are also in agreement with the information given in the TOC vs. Mo diagram (Fig. 12C). Settings in which deep waters were predominantly oxic or suboxic accumulate little authigenic Mo because the concentrations of H_2S required to convert molybdate anions into particle-reactive thiomolybdates are lacking (Helz et al., 1996). In such systems, the low concentration of Mo is due to redox conditions rather than hydrographic controls. However, in a restricted basin with low deep-water renewal, the inventory of dissolved Mo is depleted and the Mo/TOC ratio is therefore low (Algeo and Rowe, 2012). Under this context, at the La Grita Member, reducing conditions are evident and the medium Mo/TOC ratios suggest that this unit was deposited in a moderately restricted marine system (Cariaco Basin-type; Fig. 12C).

5.4.3 Marine primary productivity: Inferences from phosphorus contents

P is an important limiting nutrient in the ocean, driving primary productivity (e.g., Tyrell, 1999; Schoepfer et al., 2015). The transfer of P into sediments occurs by its incorporation into OM and fish debris or by aggregation onto clay particles or iron and manganese oxyhydroxides (Delaney, 1998). However, P burial within sediments is strongly influenced by changes in the benthic redox conditions (e.g., van Cappellen and Ingall, 1994; Ingall et al., 2005; Algeo and Ingall, 2007; Mort et al., 2007; Schoepfer et al., 2015). Indeed, dysoxic-to-anoxic bottom-water conditions not only promote enhanced preservation of organic matter but also a remobilization and release of mineral-associated phosphate and organic P into the uppermost sediments and overlying water column (van Cappellen and Ingall, 1994; Ingall et al., 2005; Mort et al., 2007). Under such conditions, the increased regeneration of P in sediments may lead to both enhanced phosphate recycling (low P burial efficiency) and increased primary productivity in a positive feedback loop (van Cappellen and Ingall, 1994; Ingall et al., 2005; Schoepfer et al., 2015).

Two main processes have been proposed to explain the supply of P to marine basins and paleoproductivity increase: (1) reworking of nearshore sediments and soils during transgression (Erbacher et al., 1996; Jarvis et al., 2002) and (2) intensified precipitation and enhanced continental weathering and runoff (Föllmi, 1996). As shown in Figure 2a, the La Grita Member represents the period of maximum flooding in the third transgressive cycle proposed by Macellari (1988), with up to 80% of regional areas flooded (Macellari, 1988). Likewise, the detrital proxies (Fig. 11) evidence that the initial rise in P contents could be correlated with increased continental runoff and weathering. Overall, both processes probably contributed to an upswing in primary productivity, as suggested by the high TOC values (up to 8%).

However, the P contents in the La Grita Member show two spikes of heavy enrichment, at 3.50 m and 8.25 m of stratigraphic depth (similar to the RSTE trend, Figs.7c and 8E). This assumes that redox conditions dominated P behaviour above a detrital effect during deposition of the La Grita Member. Thus, we hypothesize that the transgression advance and the intensification of weathering gave rise to an initial rise in P concentrations and in primary productivity in the basin. During this first stage (Figs. 7C and 8E; 0–3 m), organic matter decay and PO_4^{3-} transfer likely led to an increase in the precipitation of $P_{authigenic}$ and $P_{oxyhydroxides-Fe}$ in deep water (Mort et al., 2007). Then, progressively more anoxic conditions and the conservation of organic matter inhibited the formation of $P_{authigenic}$, decreasing the concentration of P_{total} in the La Grita sediments. The recycling of phosphate and other nutrients from deep to surface water probably kept primary productivity high during and after OAE-1d.

Alternatively, P-rich intervals might also be related with a high abundance of preserved fish debris within the sediment (Schenau and De Lange, 2001; Montero-Serrano et al., 2015). Indeed, large amount of fish debris and P-rich autigenic phases have also been reported in previous petrographic analyses of the La Grita Member (Rodríguez, 1989).

5.5. Depositional model of the La Grita Member

The depositional system from the mid to late Cretaceous in western Venezuela was heavily influenced by the topographic landscape. The basin was characterized by emergent zones that acted as paleobathymetric barriers, giving rise to a series of semi-restricted basins with poor water circulation (Macellari, 1988; Lugo and Mann, 1995; Erlich et al., 1999a,b; Fig. 13A). Based on the geochemical data presented in this

673   study, we propose a depositional and environmental conditions model for the La Grita

674   Member (Fig. 13B). This model is detailed in the stages described below.

675   In the stage 1 the third transgressive cycle proposed by Macellari (1988) starts with

676   the deposition of the sandy sediments of the Aguardiente Formation in a littoral and/or

677   fluvial-coastal setting. This more proximal setting is characterized by oxic bottom

678   waters (low values of RSTE enrichment factors) and is influenced by terrestrial

679   organic matter evidenced by more positive $\delta^{13}C_{org}$ values (-26‰ to -23‰; Dean et al.,

680   1986; Meyers et al., 2006).

681   Subsequently, during stage 2 the acceleration of the hydrological cycle led to

682   increased runoff, as indicated by the meaningful increase in the detrital proxies (Fig.

683   11). This process probably generated an increase in nutrient availability and thus in

684   primary productivity. The enhanced runoff, together with basin deepening, led to a

685   thermohaline stratification and decrease in dissolved oxygen in the bottom water,

686   thereby favouring the preservation of organic matter. This rapid increase in primary

687   productivity created a rise in dissolved ^{13}C in ocean water since ^{12}C is preferentially

688   captured by organisms. The establishment of these anoxic bottom water conditions

689   caused strong RSTE enrichment in the La Grita sediments (10 < EF < 1000; Fig. 8A-

690   B) during the initial stages of the transgression.

691   In a more advanced stage of the transgression (stage 3), anoxic bottom water

692   conditions persisted, and the recycling of phosphate and other nutrients from deep

693   water probably kept primary productivity high. The semi-restriction of the basin due

694   to topographic highs and the increased water stratification (as illustrated by the Mo-U

695   and Mo-TOC co-variation patterns; Fig. 12B-C) probably prevented high metal

696   concentrations in the deep water (EF ~ 10; basin reservoir effect).

697   In the stage 4 the sequence is truncated due to uplift of the basin associated with

698 the collision of the Pacific volcanic arc with the continental crust of South America

699 (Canache et al., 1994), thereby producing a period of no deposition — a hiatus. This

700 event was accompanied by partial oxygenation of deep water, as revealed in the

701 decrease in the redox balance (Fig. 8G).

702   Reactivation of the basin's compression and regional flexural downwarping,

703 leading to a rapid re-establishment of sea level (Canache et al., 1994; stage 5). This

704 allowed anoxic conditions to reign and a strong enrichment of trace metals right after

705 the hiatus. The detrital proxies suggest that deposition of the Seboruco Member was

706 accompanied by deceleration of the hydrological cycle and, therefore, by decreased

707 primary productivity.

708

6. Conclusions
709

710   In this study, we present a new multi-proxy record (including biostratigraphy,

711 carbon-isotope, as well as major, minor, and trace metals) of the late Albian OAE-1d

712 interval from the La Grita Member (Capacho Formation) in southwestern Venezuela.

713 This multi-proxy record yields the following generalizations and conclusions:

714   (1) The biostratigraphic data assessed indicate that the La Grita sediments were

715   deposited at 100–98 Ma (*Rotalipora appenninica* Zone; late Albian), the same

716   age reported for OAE-1d. Furthermore, this analysis revealed a hiatus at the

717   lower Cenomanian boundary that is probably related to the collision of the

718   Pacific Arc with the South American Continental Plate.

719   (2) The positive $\delta^{13}C_{carb}$ excursion (~1‰) and higher TOC values recorded in the

720   La Grita Member are associated with the development of the OAE-1d in

721   western basin of Venezuela.

(3) The detrital proxies (notably, siliciclastic balance, Rb/Sr, Ti/Al and CIA index) support the idea that (a) the greenhouse climate prevailing during the OAE-1d led an acceleration of the hydrologic cycle and an increase in continental weathering rates, and (b) the orbital forcing likely also modulated the equatorial monsoonal activity during the late Albian.

(4) With the exception of the Aguardiente Formation, the redox-sensitive proxies [notably, redox balance, RSTE enrichment factors, pyrite content, and ternary plots TOC-S-Fe] indicate anoxic (and possibly euxinic) bottom-water conditions during deposition of the La Grita and Seboruco members. Under such conditions, the release of phosphorus from the sediments into the water column likely sustained the primary productivity, acting as a positive feedback loop.

(5) Mo-U and Mo-TOC co-variation patterns suggest a semi-restricted basin setting (similar to the Cariaco Basin) for the deposition of the La Grita sediments. Thus, the moderate accumulation of redox-sensitive trace metals recorded during the OAE-1d likely result from a basin reservoir effect.

Taken as a whole, our geochemical data complement scarce existing data from northern South America for Albian-Cenomanian records and provide a solid record of the major paleoenvironmental changes that fostered deposition of the La Grita Member during the development of the OAE-1d.

Figure captions

1207

1208 **Fig. 1**. Palaeogeographical maps of the Albian-Cenomanian boundary (redrawn from

1209 Vrielynck and Bouysse, 2003) showing the La Grita Member studied herein and the

1210 locations of the well-dated DSP and ODP sites (black dots) that recorded the OAE-1d

1211 (Wilson and Norris, 2001).

1212

1213 **Fig. 2**. **(A)** General chart of stratigraphic correlation of the Cretaceous in western

1214 Venezuela (synthesized by Erlich et al., 1999b); **(B)** Location maps; **(C)** the different

1215 deposition cycles (Macellari, 1988), global sea level changes (Sliter, 1976), and the

1216 percentage of flooded areas in northern South America (Maceralli, 1988); **(D)** the

1217 proposed stratigraphic analysis for the La Grita Member (Méndez et al., 2015). The

1218 Sequence K2 refers to the depositional sequence Albian–lower Cenomanian described

1219 by Parnaud et al. (1995) and includes the Lisure, Maraca, lower Capacho,

1220 Aguardiente, and basal Escandalosa formations. TRS: Transgressive ravinement

1221 surface, MFS: Maximun flooding surface, HST: Highstand systems tract, TST:

1222 Transgressive systems tract.

1223

1224   **Fig. 3**. Stratigraphic column with the distribution of the samples studied herein and

1225   outcrop of the La Grita Member on the Guaruríes River (Zea, state of Mérida,

1226   Venezuela).

1227

1228   **Fig. 4**. Microphotographs of the planktonic foraminifer species identified in the study

1229   section: **(A)** *Rotalipora* cf *Ticinesis* (ZEARG-185), **(B)** *Hedbergella delrioensis*

1230   (ZEARG-185), **(C)** *Hedbergella rischi* (ZEARG-165), **(D)** *Hedbergella planispira*

1231   (ZEARG-85), **(E)** *Clavihedbergella simplex* (ZEARG-155), **(F)** *Ticinella raynaudi*

1232   (ZEARG-125), **(G)** *Ticinella roberti* (ZEARG-112), and **(H)** *Ticinella primula*

1233   ZEARG-155).

1234

1235   **Fig. 4.** Continuation: **(I)** *Whiteinella báltica* (ZEARG-65), **(J)** *Biticinella bregginesis*

1236   (ZEARG-145), **(K)** *Globigerinelloides caseyi* (ZEARG-95), **(L)** *Globigerinelloides*

1237   *ultramicrus* (ZEARG-115), **(M)** *Globigerinelloides bentonesis* (ZEARG-185), **(N)**

1238   *Planomalina buxtorfi* (ZEARG-112), **(O)** *Heterohelix morenami* (ZEARG-85), and

1239   **(P)** *Heterohelix reussi* (ZEARG-85). All the microphotographs were taken with

1240   parallel nichols.

1241

1242   **Fig. 5**. Distribution of the main species of marker and/or indicator planktonic

1243   foraminifera and biostratigraphic Zones identified in the La Grita Member. Note that

1244   the interval corresponding to the early Cenomanian (*Rotalipora brotzeni-Rotalipora*

1245   *reicheli* Zones) cannot be defined due to a lack of biostratigraphic data.

1246

1247   **Fig. 6**. Stratigraphic distribution of isotope compositions of **(A)** $\delta^{13}C_{carb}$, **(B)** $\delta^{18}O_{carb,}$

1248   **(C)** $\delta^{13}C_{org}$, **(D)** total organic carbon (TOC), and **(E)** relative sea level in the La Grita

1249   section. The shaded interval indicates the positive carbon isotope excursion

1250   (*Rotalipora appenninica* Zone) related to OAE-1d.

1251

1252   **Fig. 7**. **(A-E)** Stratigraphic profiles of the major geochemical associations obtained by

1253   compositional Q-mode cluster analysis. The shaded interval indicates the positive

1254   carbon isotope excursion (*Rotalipora appenninica* Zone) related to OAE-1d. **(F)**

1255   Dendrogram of association of variables obtained by applying Ward clustering

1256   algorithm based on the variation matrix of elemental geochemical dataset.

1257

1258   **Fig. 8**. Stratigraphic distribution of the main redox proxies obtained from the La Grita

1259   Member. **(A-B)** Element enrichment factors (EF) for the redox associations; **(C)**

1260   relative content of pyrite (%); **(D)** sulfur total (%); **(E)** P enrichment factors; **(G)**

1261   redox balances; Balances are represented according to Eq. (1); **(H)** relative sea level

1262   in the La Grita section. The shaded interval indicates the positive carbon isotope

1263   excursion (*Rotalipora appenninica* Zone) related to OAE-1d.

1264

1265   **Fig. 9**. $\delta^{13}C_{carb}$ vs. $\delta^{18}O_{carb}$ correlation diagram for the various units studied, indicating

1266   zones altered by different diagenic processes (according to Schobben et al., 2016).

1267

1268   **Fig. 10**. Overview of Albian/Cenomanian carbon-isotope records showing OAE-1d

1269   (shaded interval) in different basins worldwide.

1270

1271   **Fig. 11**. Stratigraphic distribution of the main detrital proxies obtained from the La

1272   Grita Member. **(A)** detrital balance (Sc, K, Al, Rb, Si, Zr, Hf, Ti, Nb). Balances are

1273   represented according to Eq. (1). **(B)**. Rb/Sr; **(C)** Ti/Al; (D) CIA index. The shaded

interval indicates the positive carbon isotope excursion (*Rotalipora appenninica* Zone) related to OAE-1d.

Fig. 12. **(A)** TOC–S–Fe ternary diagram corresponding to the La Grita Member used to discriminate between different redox facies (La Luna data are from Lo Mónaco et al., 2002). **(B)** U-Mo covariation for evaluating redox and oceanographic controls in the La Grita Member, based on the model proposed by Tribovillard et al. (2009). **(C)** Mo-TOC covariation for the La Grita samples, indicating some trends for modern restricted and semi-restricted basins (modified after Algeo and Rowe, 2012).

Fig. 13. Depositional model of the La Grita Member: **(A)** Physiography and a-a' cross-section of basin, and **(B)** model to illustrate the various stages and geochemical processes characteristic during the development of the OAE-1d. OMZ: oxygen minimum zone.
